Abstract

In this paper, a new randomized solver for noisy unconstrained black box optimization, called VRBBON, is discussed. Complexity bounds in the presence of noise for nonconvex, convex, and strongly convex functions are studied. Two effective ingredients of VRBBON are an improved derivative-free line search algorithm with many heuristic enhancements and quadratic models in adaptively determined subspaces. A recommendation is made as to which solvers are robust and efficient based on dimension and noise level. It turns out that VRBBON is more robust and efficient than the state-of-the-art solvers, especially for medium and high dimensions.

Keywords: Noisy black box optimization, heuristic optimization, randomized line search method, complexity bounds, sufficient decrease

2020 AMS Subject Classification: 90C15; 90C30; 90C56

1 Introduction

We consider the problem of finding a minimizer of the smooth real-valued function $f: \mathbb{R}^n \to \mathbb{R}$

$$\min_{x \in \mathbb{R}^n} f(x),\tag{1}$$

where f is known only by a noisy oracle which, for a given $x \in \mathbb{R}^n$, gives an approximation $\tilde{f}(x)$ to the exact function value f(x), contaminated by noise. This problem is called the noisy black box optimization (BBO) problem. We denote by g(x) the unknown exact gradient vector of f at x and by $\tilde{g}(x)$ its approximation, and by B(x) the Hessian matrix of f at x and by $\tilde{B}(x)$ its approximation. The algorithm uses no knowledge of g, the Lipschitz constants of f, the structure of f, and the statistical properties of noise. Noise may be deterministic (caused by modelling, truncation, and/or discretization errors) or stochastic (caused by inaccurate measurements or rounding errors).

A complexity bound of an algorithm for the noisy BBO problem (1) is an upper bound on the number of function evaluations to find an approximate point near the local optimizer whose unknown exact gradient norm is below a given fixed threshold $\omega > 0$ (which is unknown to us but appears in our complexity bound) and whose function value is as small as possible compared to the initial function value. In practice, such a point is unknown because the Lipschitz constants and gradients are unknown. However, the inexact function value of this point is equal to or better than a point whose gradient is small only near a global optimizer. To obtain such a complexity bound, one assumes that any noise estimate $\tilde{f}(x)$ of f at $x \in \mathbb{R}^n$ satisfies

$$|\tilde{f}(x) - f(x)| \le \omega. \tag{2}$$

To determine which solvers are competitive for the noisy BBO problem (1), two main tools are used: robustness (highest number of problems solved) and efficiency (lowest relative cost of function evaluations). The data profile of Moré & Wild [32] and the performance profile of Dolan & Moré [14] are used to compare these solvers in terms of robustness and efficiency, respectively. A solver with the highest number of solved problems is called robust and with the lowest relative cost of function evaluations is called efficient.

1.1 Related work

There are many efficient and robust methods for the noisy BBO problem (1). LARSON et al. [28] have discussed these methods and their complexity bounds (if any). These methods are based on line search, direct search, model-based, etc., and are either deterministic or randomized or both. We focus here on

- line search methods, e.g., see [28, Section 2.3.4] (GRIPPO & RINALDI [20], GRIPPO & SCIANDRONE [21], LUCIDI & SCIANDRONE [30], and NEUMAIER et al. [33]),
- model-based methods, e.g., see [28, Section 2.2] (BANDEIRA et al. [3], BUHMANN [8], CONN & TOINT [10], GRATTON et al. [17, 18], GRATTON et al. [19], POWELL [35, 36], HUYER & NEUMAIER [24], and WILD et al. [40]),
- randomized methods, e.g., see [28, Section 3.2] (AUDET & DENNIS [1], BANDEIRA et al. [3], DINIZ-EHRHARDT et al. [13], GRATTON et al. [17, 18], and VAN DYKE & ASAKI [39]).

Two good references for studying the efficiency and robustness of these solvers are Rios & Sahinidis [37] and Kimiaei & Neumaier [27]. As a result of their numerical results, some efficient and robust solvers are:

- Line search: VRBBO (randomized) by Kimiaei & Neumaier [27], SDBOX (deterministic) by Lucidi & Sciandrone [30], FMINUNC (Wolfe conditions along standard BFGS directions) by Matlab Optimization Toolbox.
- Nelder-Mead: NMSMAX by HIGHAM [22].
- Direct search: DSPFD (randomized) by GRATTON et al. [17], BF0 by PORCELLI & TOINT [34], and MCS (multi coordinate search) by HUYER & NEUMAIER [23].
- Model-based: BCDFO by GRATTON et al. [19], UOBYQA and NEWUOA by POWELL [35, 36], and SnobFit by HUYER & NEUMAIER [24].
- \bullet Covariance matrix adaptation evolution: CMAES (stochastic) by Auger & Hansen [2].

Other covarince matrix adaptation evolution solvers are LMMAES (limited memory) by LOSHCHILOV et al. [29], fMAES (fast) by BEYER [6], and BiPopMAES (Bi-Population) by BEYER & SENDHOFF [7]. GRID by ELSTER & NEUMAIER [15] is another model-based solver for bound constrained noisy black box optimization problems.

We here discuss the advantages and disadvantages of the above solvers:

- Model-based solvers are only effective for problems in low dimensions in the presence of noise, but they cannot handle problems in medium to high dimensions because n(n+3)/2 sample points are needed to construct fully quadratic models.
- Line search solvers (VRBBO and SDBOX) are more efficient and robust than direct search solvers because they use extrapolations, which are an accelerated component of these line search methods. Extrapolations expand step sizes along with fixed directions until the inexact function values are improved.

Both direct search and line search solvers can handle problems in small to large dimensions. Although another line search solver, FMINUNC, is effective in the noiseless case, it is numerically inefficient in the presence of noise because a finite difference technique for estimating the gradient leads to misleading information and poor quasi-Newton directions (for similarities and differences of our line search based algorithm with the mentioned solvers, see Sections 2.1 and 2.2).

- Nelder–Mead solvers are effective for small scale problems; however, they can also handle problems in medium dimensions, although their efficiency and robustness decrease with increasing dimension, e.g., TORCZON [38] and WRIGHT [41].
- LOSHCHILOV et al. [29] discussed and showed that solvers based on full covariance matrix adaptation evolution strategies are costly for large problems because the covariance matrices are stored. Therefore, they proposed a limited memory covariance matrix adaptation evolution method (LMMAES) for large scale problems. However, this method is not effective for large scale problems because it ignores some parts of the covariance matrix, see Section 7.5.3.

1.2 Known limit accuracy and complexity bounds

In this section, we discuss the achievable limit accuracy and complexity bounds of several well-known black box optimization methods under standard assumptions:

- (A1) The function f is continuously differentiable on \mathbb{R}^n , and its gradient is Lipschitz continuous with Lipschitz constant L.
- (A2) The level set $\mathcal{L}(x^0) := \{x \in \mathbb{R}^n \mid f(x) \le f(x^0)\}$ of f at x^0 is compact.
- (A3) The uncertainty of the function value $\tilde{f}(x)$ obtained by a noisy oracle is globally bounded by a small threshold $\omega > 0$, i.e., the condition (2) holds. In the noiseless case $\omega = 0$ (A3) implies $\tilde{f} = f$.
- (A2) implies that

$$\widehat{f} := \inf\{f(x) \mid x \in \mathbb{R}^n\} = f(\widehat{x}) > -\infty \tag{3}$$

for any global minimizer \hat{x} of (1).

Given a positive scaling vector $s \in \mathbb{R}^n$ (fixed in throughout the paper), we define the scaled 2-norm ||p|| of $p \in \mathbb{R}^n$ and the dual norm $||g||_*$ of $g \in \mathbb{R}^n$ by

$$\|p\| := \sqrt{\sum_i p_i^2/s_i^2} \ \ \text{and} \ \ \|g\|_* := \sqrt{\sum_i s_i^2 g_i^2}.$$

For the noiseless case, see Larson et al. [28, Table 8.1] for a summary of known results on worst-case complexity and corresponding references. To obtain $||g(x)||_* \le \varepsilon$ (under the assumptions (A1) and (A2)), one needs

- $\mathcal{O}(\varepsilon^{-2})$ function evaluations for the general case,
- $\mathcal{O}(\varepsilon^{-1})$ function evaluations for the convex case,
- $\mathcal{O}(\log \varepsilon^{-1})$ function evaluations for the strongly convex case. In all cases, the factors are ignored. Randomized algorithms typically have complexity bounds that are a factor n better than those of deterministic algorithms, see [3].

In the presence of noise, the limit accuracy of some algorithms was investigated:

 \bullet For the unconstrained case, Berahas et al. [4] proved convergence results for the problem (1) when f is strongly convex. Assuming strong convexity of f and boundedness of noise in the approximation gradient, they proved that a quasi-Newton method with a fixed step size has linear convergence to a neighborhood of the solution; the gradient is estimated by the forward or central finite differences. Under the additional assumption (A3), they showed that a quasi-Newton method with step sizes found by a relaxed Armijo line search, called FDLM, has asymptotic accuracy

$$f - \widehat{f} = \mathcal{O}(L\omega). \tag{4}$$

CHEN [9] proposed a randomized algorithm with Gaussian directions and estimated step sizes, called STRRS for various types of noise, one of which is discussed here. Under the assumptions

- (i) $\tilde{f}(x) f(x) = \omega(x; \zeta)$ is a stochastic noise component, where ζ is a random vector with probability distribution $\Pr(\zeta)$,
- (ii) for all $x \in \mathbb{R}^n$, ω is independent and identically distributed (i.i.d.) with bounded variance $var(\omega) > 0$,
- (iii) for all $x \in \mathbb{R}^n$, noise is unbiased, i.e., $\mathbf{E}_{\zeta}(\omega) = 0$,
- (iv) f is convex and (A1) holds,
- (v) $var(\omega) \le \mathcal{O}(\varepsilon/n)$,

STRRS needs at most $\mathcal{O}(nL\varepsilon^{-1})$ to ensure that

$$x^N := \operatorname*{argmin}_x \{f(x) \mid x \in \{x^0, \cdots, x^N\}\}$$

satisfies $\mathbf{E}[f(x^N)] - \widehat{f} \leq \varepsilon$.

• For the bound constrained case, Elster & Neumaier [15] introduced a grid algorithm, called GRID. Here we restrict their results to the unconstrained case. Under the assumptions (A1)–(A3), [15, Theorem 2] ensures that there exists a constant C_n such that

$$||g(x^k)||_* \le C_n(2\omega/h^k + Lh^k)$$
 for $x^k \in \mathbb{R}^n$

at the end of the kth refinement step, where h^k denotes the kth grid size. If $h^k := \Theta(\sqrt{\omega})$, then the best order of magnitude can be obtained at least for a point with the gradient

$$||g||_* = \mathcal{O}(C_n\sqrt{\omega}). \tag{5}$$

The dependence of C_n on n is not specified. Under the same assumptions, Lucidi & Sciandrone [30] constructed a derivative-free line search algorithm, called SDBOX, using only the coordinate directions. They proved that, for any k,

$$\|g(x^k)\|_* = \mathcal{O}\left(n^{3/2}L\mathbf{a}_{\max}^k + \frac{n\omega}{\mathbf{a}_{\min}^k}\right), \text{ for } x^k \in \mathbb{R}^n.$$

Here \mathbf{a}_{\min}^k and \mathbf{a}_{\max}^k are minimum and maximum values, respectively, for the n step sizes used along the coordinate directions in the iteration k. If $\mathbf{a}_{\max}^k := \Theta(\sqrt{\omega})$, the best order of magnitude can be obtained at least for a point with the gradient

$$||g||_* = \mathcal{O}\left(n^{3/2}\sqrt{\omega}\right). \tag{6}$$

The order of ω in (6) is the same as in (5) but their factors are different.

As stated in the introduction, $\tilde{g}(x)$ stands for the estimated gradient at x. Berahas et al. [5] used the line search discussed in [4]

$$\tilde{f}(x + \alpha p) \le \tilde{f}(x) + c_1 \alpha p^T \tilde{g}(x) + 2\omega \text{ with } 0 < c_1 < 1$$
 (7)

but step sizes are updated in a different way. Here $\tilde{f}(x) - f(x) = \omega(x; \zeta)$ is stochastic where ζ may be either dependent, independent or identical. Under the assumptions (A1)–(A3) (neither stochastic noise nor reduction or control of noise is assumed) and

norm condition:
$$\|\tilde{g}(x) - g(x)\| \le \theta \|g(x)\|$$
, for some $0 < \theta < 1$, (8)

they found for all cases (nonconvex, convex, and strongly convex) that the expected complexity results for a given accuracy $\varepsilon > 0$ (sufficiently larger than ω) exceed a near optimal neighborhood to noise. In the general case, $\mathcal{O}(\varepsilon^{-2})$ function evaluations with $\mathbf{E}(\|g\|_*) \leq \varepsilon$ are used in the worst case. In the convex and strongly convex cases, $\mathcal{O}(\varepsilon^{-1})$ and $\mathcal{O}(\log \varepsilon^{-1})$ function evaluations with $\mathbf{E}(\|g\|_*) \leq \varepsilon$ and $\mathbf{E}(f - \widehat{f}) \leq \varepsilon$, respectively, are used in the worst case.

2 An overview of our method

We propose a new solver for noisy unconstrained black box optimization — called *Vienna noisy randomized black box optimization* (VRBBON). Its basic

7

version is called VRBBON-basic. Following the classifications of LARSON et al. [28] and RIOS & SAHINIDIS [37], our new solver VRBBON is a local model-based randomized solver.

The VRBBON package is publicly available at

https://github.com/GS1400/VRBBON/archive/refs/heads/main.zip.

Supplemental information can be found in **suppMat.pdf** on the VRBBON web site with new practical enhancement and details of the codes compared.

2.1 Similarity of VRBBON with other solvers

- (i) (Algorithmic) VRBBON is an adaptation of our recent solver VRBBO (KIMIAEI & NEUMAIER [27]) to the noisy case, while retaining the main structure of VRBBO, namely a multi-line search algorithm.
- (ii) (*Practical enhancement*) VRBBON uses only one of the practical enhancements of VRBBO, namely random subspace directions.
- (iii) (Complexity results) In all cases, the order of ω in our bounds is the same as in Berahas et al. [5].

2.2 Difference between VRBBON and other solvers

- (i) (Algorithmic) VRBBON repeatedly calls an improved decrease search called DS (implemented in Section 1.8 of suppMat.pdf) whose basic version is DS-basic (described in Section 4). DS uses an improved multi-line search algorithm called MLS (implemented in Section 1.7 of suppMat.pdf) that is likely to reduce function values, whose basic version is MLS-basic (described in Section 4). MLS uses heuristics to find and update step sizes that are significantly different from the way step sizes are updated in other solvers, e.g., SDBOX, VRBBO, and FMINUNC. After a few calls to MLS by DS, without decreasing the inexact function value, step sizes may become too small if noise is high. All derivative free line search methods have this drawback when noise is high. To remedy this, DS reconstructs step sizes heuristically (lines 29-38 of DS in Section 1.8 of suppMat.pdf).
- (ii) (New practical enhancements) Unlike VRBBO, SDBOX, and FMINUNC, VRBBON uses many new practical enhancements (Section 1 of suppMat.pdf). This solver constructs surrogate quadratic models in adaptively determined subspaces that can handle medium and large scale problems (Section 1.4 of suppMat.pdf). Although these models have lower accuracy in higher dimensions, their usefulness has been confirmed in extensive numerical experiments in the presence of strong noise. MLS is performed along the new directions, either random approximate coordinate (Section 1.1 of suppMat.pdf), perturbed random (Section 1.5 of suppMat.pdf) or improved trust region directions

(Section 1.6 of suppMat.pdf):

- It is well known that the complexity of randomized black box optimization methods is better than that of deterministic methods by a factor of n in the worst case (cf. [3]); therefore, using random directions seems preferable to using deterministic ones.
- \bullet Even better directions than random directions are random approximate coordinate directions.
- Improved trust region directions are found by minimizing surrogate quadratic models in adaptively determined subspaces within a trust region.
- Perturbed random directions are perturbations of random directions by scaled approximate descent directions in adaptively determined subspaces. (iii) (Complexity results for VRBBON-basic) For VRBBON-basic that uses only scaled random directions and no practical enhancements, we prove the complexity results with probability arbitrarily close to one for nonconvex, convex, and strongly convex functions in the presence of noise. In contrast to the method of Berahas et al. [5], which uses the norm condition (8), our line search does not use the term $c_1 \alpha p^T \tilde{g}(x)$ of the condition (7), but $\gamma \alpha^2$ with $0 < \gamma < 1$ because the estimation of the gradient may be inaccurate in the presence of high noise, leading to failure of the line search algorithm, e.g., see behaviour of FMINUNC in Section 7. However, we estimate the gradient to generate different heuristic directions in Section 1 of suppMat.pdf. Therefore, we obtain our complexity bound regardless of the norm condition (8) since the nature of the line search algorithms is different. On the other hand, our bounds are obtained with high probability. Therefore, they are more likely to be appropriate and differ from the results of BERAHAS et al. [5], which are valid only in expectation.
- (iv) (Complexity results for VRBBON) To obtain the complexity results for VRBBON (implemented version), random scaled directions should be used; this is not a problem to guarantee the complexity results when other directions are used. In fact, the order of the complexity bounds of VRBBON does not change for all cases after applying the heuristic improvements, although the constant factors may be become larger, as in the deterministic cases (as mentioned in Section 2.2(ii) the complexity of deterministic black box optimization methods is in the worst case by a factor n worse than that of randomized methods). However, the robustness and efficiency of VRBBON are numerically increased.

2.3 Organization

In Section 3 we discuss how to generate scaled random directions. Then, in Section 4, we describe a basic version of VRBBON using scaled random directions. Complexity results of a basic version of VRBBON for all cases with a given probability arbitrarily close to one in the presence of noise are proved in Section 5. Complexity results of VRBBON (implemented version) are discussed in Section 6. Section 7 provides a comparison between VRBBON and the solvers

discussed in Section 1.1 on the 549 unconstrained CUTEst test problems from the collection of Gould et al. [16] and makes a recommendation as to which solvers are robust and efficient based on dimension and noise level. It turns out that VRBBON is more robust and efficient, especially for medium and high dimensions.

3 Search direction

In this section it is described how to generate random directions. Then it is shown that these directions satisfy the two-sided angle condition (defined below) with probability at least half.

We define a standard random direction as a random direction p drawn uniformly i.i.d. in $[-\frac{1}{2},\frac{1}{2}]^n$. As explained in the introduction, i.i.d. stands for independent and identically distributed. A scaled random direction is a standard random direction p scaled by $\gamma_{\rm rd}/\|p\|$, where $0 < \gamma_{\rm rd} < 1$ is a tiny tuning parameter, resulting in $\|p\| = \gamma_{\rm rd}$.

The scaling of the direction p by $\gamma_{\rm rd}$ is the same as the scaling of the direction p by δ in [27, (17)]. Therefore, our scaled random direction is the same as the scaled random direction obtained by [27, (17)]. Thus, the next result holds for any scaling vector $s \in \mathbb{R}^n$ (defined in Section 1.2), although we do not intend to estimate s in this paper; it is assumed that $s_i = 1$ for $i = 1, 2, \dots, n$.

Essential for our complexity bounds is the following result (Proposition 2 in [27]) for the unknown gradient g(x) of f(x) at $x \in \mathbb{R}^n$.

Proposition 1 Any scaled random direction p satisfies the inequality

$$\Pr(\|g(x)\|_*\|p\| \le 2\sqrt{cn}|g(x)^T p|) \ge \frac{1}{2}$$
 (9)

with a positive constant $c \le 12.5$. The approximate value for the constant c has been discussed in [27, Section 9.1].

The condition (9) is called two-sided angle condition because we cannot check whether any scaled random direction is a descent direction or not. Hence, instead of searching along one ray $\alpha > 0$ only, our line search allows to search the line $x + \alpha p$ in both directions ($\alpha \in \mathbb{R}$).

4 VRBBON-basic, a basic version of VRBBON

This section discusses a basic randomized method for the noisy BBO problem (1), called VRBBON-basic.

VRBBON-basic counts with $k \in \mathbb{N}_0 := \mathbb{N} \cup \{0\}$ the number of calls to DS-basic and with $t \in \{1, 2, \cdots, T_0\}$ the number of calls to MLS-basic. Here $1 \leq T_0 < \infty$ is a tuning parameter. Moreover, MLS-basic counts the number of scaled random directions by $r \in \{1, 2, \cdots, R_m\}$, whose upper bound $(2 \leq R_m < \infty)$ is a tuning parameter. To simplify our algorithms, once all tuning parameters are given in line 1 of VRBBON-basic, not mentioned as input.

 $n_{\mathtt{succ}}^{\mathtt{MLS}}$ counts the number of reductions in the inexact function values by $\mathtt{MLS-basic}$, while $n_{\mathtt{succ}}^{\mathtt{DS}}$ counts the number of reductions in the inexact function values by $\mathtt{DS-basic}$, which is the total number of reductions in inexact function values by $\mathtt{MLS-basic}$.

An iteration of MLS-basic is called successful if a reduction of the inexact function value is found; otherwise it is called unsuccessful. If no reduction of the inexact function value is found after R_m iterations ($n_{\tt succ}^{\tt MLS}=0$), MLS-basic is called inefficient; otherwise, it is called efficient.

An iteration of DS-basic is called successful if MLS-basic is efficient $(n_{\tt succ}^{\tt MLS}>0)$; otherwise it is called unsuccessful. DS-basic is called efficient if it has at least one successful iteration $(n_{\tt succ}^{\tt DS}>0)$; otherwise it is called inefficient. An iteration of VRBBON-basic is called successful if DS-basic is efficient $(n_{\tt succ}^{\tt DS}>0)$; otherwise, it is called unsuccessful.

We denote by x_{best} the overall best point and by $\tilde{f}_{\text{best}} := \tilde{f}(x_{\text{best}})$ the overall best inexact function value of VRBBON-basic, i.e., the final best point and its inexact function value found by DS-basic. Indeed, the overall best point is an ε -approximate stationary point of the sequence x^k $(k=1,2,3,\cdots)$ after VRBBON-basic terminates at a finite number of iterations.

VRBBON-basic initializes the number $n_{\rm f}$ of function evaluations and the initial step size $\delta_0 := \delta_{\rm max}$, which is a tuning parameter, and computes the inexact function value $\tilde{f}(x^0)$ at the initial point x^0 in line 2. In each iteration, VRBBON-basic calls DS-basic to hopefully find a reduction of the inexact function value (line 4). Once the step size δ_k is below the minimum threshold $0 \le \delta_{\rm min} < 1$ (line 5), which is a tuning parameter, VRBBON-basic terminates with the overall best point $x_{\rm best} := x^{k+1}$ and its inexact function value $\tilde{f}(x_{\rm best}) := \tilde{f}(x^{k+1})$ in the (k+1)th iteration. Otherwise, if DS-basic cannot find a reduction of the inexact function value (i.e., $n_{\rm succ}^{\rm DS} = 0$) the step size δ_{k+1} is reduced by a factor of Q > 1 (line 7), which is a tuning parameter; otherwise, δ_{k+1} is δ_k (line 9). VRBBON-basic tries to find an ε -approximate stationary point $x_{\rm best}$ that satisfies $\|g(x_{\rm best})\|_* \le \varepsilon$ for a threshold $\varepsilon = \sqrt{\omega}$ before the condition $\delta_k \le \delta_{\rm min}$ is satisfied. When $\delta_{\rm min} = 0$ and since the gradient $g(x_{\rm best})$ is unknown, nfmax is required as an upper bound on the number of function evaluations for a finite termination.

Algorithm 1 VRBBON-basic, a basic randomized method for noisy BBO problems

1: Tuning paramters: Q>1 (factor for reducing δ_k), $0<\gamma_{\rm rd}<1$ (parameter for scaling random directions), $0<\gamma<1$ (parameter for line search), $\gamma_e>1$ (factor for updating step size inside MLS-basic), $\delta_{\rm max}>0$ (initial value for δ_k), $0\leq\delta_{\rm min}\leq1$ (minimum threshold for δ_k), $0<\eta<\frac{1}{2}$ (parameter for R_m), $R_m:=\lceil\log_2\eta^{-1}\rceil\geq2$ (number of random direction in each MLS-basic), $T_0\geq1$ (number of calls to MLS-basic by DS-basic).

```
2: Set n_f := 1 and \delta_0 := \delta_{\max}. Then compute \tilde{f}(x^0);
     for k = 0, 1, 2, \cdots do
            \text{run}\;[x^{k+1},\;\tilde{f}(x^{k+1}),\;n_{\texttt{succ}}^{\texttt{DS}},\;n_{\texttt{f}}] = \texttt{DS-basic}(\delta_k,\;x^k,\;\tilde{f}(x^k),\;n_{\texttt{f}},\;\texttt{nfmax});
 4:
            if \delta_k \leq \delta_{\min}, set x_{\text{best}} := x^{k+1} and \tilde{f}_{\text{best}} := \tilde{f}(x^{k+1}); stop; end if
 5:
            if n_{\text{succ}}^{\text{DS}} is zero then
                                                                              \triangleright the kth iteration is unsuccessful
 6:
                  set \delta_{k+1} := \delta_k/Q;
                                                                                                             \triangleright \delta_{k+1} is reduced
 7:
                                                                                   \triangleright the kth iteration is successful
            else
 8:
                  set \delta_{k+1} := \delta_k;
                                                                                                       \triangleright \delta_{k+1} remains fixed
 9:
            end if
10:
11: end for
```

If the (k+1)th iteration of VRBBON-basic is unsuccessful $(n_{\mathtt{succ}}^{\mathtt{DS}}=0)$, then $x^{k+1}=x^k$ and $\tilde{f}(x^{k+1})=\tilde{f}(x^k)$. If $n_{\mathtt{succ}}^{\mathtt{DS}}>0$, which is an output of DS-basic (line 4), then the (k+1)th iteration of VRBBON-basic is successful.

DS-basic generates the sequences y^t and $\tilde{f}(y^t)$ $(t=1,\cdots,T_0)$. First, it initializes the number $n_{\mathtt{succ}}^{\mathtt{DS}}$ of successful iterations of DS-basic in line 12 and then initializes two sequences y^t and $\tilde{f}(y^t)$ $(t=1,\cdots,T_0)$. Subsequently, DS-basic has T_0 calls to MLS-basic to find reductions of the inexact function values in lines 14-17, while counting the number of successful iterations by $n_{\mathtt{succ}}^{\mathtt{DS}}$ in line 16. If $n_{\mathtt{succ}}^{\mathtt{DS}} = 0$, then $x^{k+1} = y^{T_0} = x^k$ and $\tilde{f}(x^{k+1}) = \tilde{f}(y^{T_0}) = \tilde{f}(x^k)$ (line 18). Otherwise, at least one reduction of the inexact function value is found and so $x^{k+1} = y^{T_0} \neq x^k$ and $\tilde{f}(x^{k+1}) = \tilde{f}(y^{T_0}) < \tilde{f}(x^k)$ (line 18).

```

MLS-basic generates the sequences z^r and $\tilde{f}(z^r)$ $(r=1,\cdots,R_m)$. It initializes the extrapolation step size in line 19 and the number of successful iterations in line 20, then initializes z_{best} (the point found in the (t-1)th iteration of DS-basic) and its inexact function value $\tilde{f}(z_{\text{best}})$ in line 21. MLS-basic has a for loop (lines 22-41) that includes a while loop (lines 24-34). In line 23, the rth scaled random direction p^r is computed and the Boolean variable good is evaluated as false. We discuss this further below. Then the while loop begins, containing extrapolation, which increases the convergence speed to achieve an $\varepsilon = \sqrt{\omega}$ -approximate stationary point. The goal of extrapolation is to expand the extrapolation step sizes α_r by the tuning parameter $\gamma_e > 1$ (line 29) along the fixed direction p^r and compute the corresponding trial point $z^r = z_{\text{best}} + \alpha_r p^r$ and its inexact function value $\tilde{f}(z^r)$ (line 25), as long as the condition

$$\tilde{f}(z_{\text{best}}) < \tilde{f}(z^r) - \gamma \alpha_r^2$$
 (10)

is satisfied (line 28) and the maximum number nfmax of function evaluations is not reached, where $0 < \gamma < 1$ is a tuning parameter. We denote $\tilde{f}(x)$ – $\tilde{f}(z^r)$ as the gain. Since the gain along p^r is at least $\gamma \alpha_r^2$, we say that $\gamma \alpha_r^2$ sufficient gain along p^r was found, which means that the Boolean variable good in line 29 has the value true. The rth iteration of MLS-basic is called successful if good is true, and unsuccessful otherwise. If the condition (10) is not satisfied (line 30), the rth opposite direction is chosen in line 31, since no $\gamma \alpha_r^2$ -sufficient gain is found along p^r unless it has already been used. Otherwise, the condition (10) along $\pm p^r$ is not satisfied and thus no $\gamma \alpha_r^2$ -sufficient gain is found along $\pm p^r$ (line 32). In this case, the while loop is stopped. Then, if good is true (line 35), since the extrapolation was stopped, the last point generated by the extrapolation does not provide $\gamma \alpha_r^2$ -sufficient gain along p^r , we set $\alpha_{r+1} = \alpha_r/\gamma_e$ to obtain the corresponding step size of the penultimate point $z_{\text{best}} := z_{\text{best}} + \alpha_r p^r$ (line 36), while its inexact function value $\tilde{f}(z_{\text{best}}) := \tilde{f}_e^r$ is updated and the number of successful iterations is updated by MLS-basic (line 37). Otherwise, if good is false (line 38), the extrapolation step size is reduced by γ_e in line 39. Finally, after the for loop is terminated, y^t and $\tilde{f}(y^t)$ are updated in line 42.

function $[y^t, \tilde{f}(y^t), n_{\text{succ}}^{\text{MLS}}, n_{\text{f}}] = \text{MLS-basic}(\delta_k, y^{t-1}, \tilde{f}(y^{t-1}), n_{\text{f}}, \text{nfmax})$

In addition to (A1)-(A3) to obtain our complexity results we assume the following assumption:

(A4) Given $0 < \alpha_{\min} < \infty$ (minimum threshold for step sizes in MLS-basic) and $\gamma_e > 1$, the condition $\gamma_e^{1-R_m} \delta_k \ge \alpha_{\min}$ holds.

Under the assumptions (A1)-(A4), this section discusses how VRBBON-basic is terminated after at most

• $\mathcal{O}(R_m T_0 \omega^{-1})$ function evaluations in the general case,

- $\mathcal{O}(\sqrt{n}R_mT_0\omega^{-1/2})$ function evaluations in the convex case,
- $\mathcal{O}(nR_mT_0\log(\omega^{-1}))$ function evaluations in the strongly convex case with an approximate point \tilde{x} , with a given probability arbitrarily close to 1, satisfying

$$f(\tilde{x}) \le \sup\{f(x) \mid x \in \mathbb{R}^n, \ f(x) \le f(x^0), \ \text{and} \ \|g(x)\|_* = \mathcal{O}(\sqrt{n\omega})\}.$$

As explained in the introduction, it is not clear to us which point, since the gradients and Lipschitz constants are unknown.

If $R_m=2$ and $T_0=1$ are chosen according to their definitions in line 1 of Algorithm 1, the term R_mT_0 asymptotically vanishes from the factors of our bounds (i.e., $R_mT_0\sim 1$). In this case, our bounds are better by a factor n than in the deterministic case (see Bandeira et al. [3] and Kimiaei & Neumaier [27]), but numerically these factors should be large to increase the efficiency and robustness of our algorithm. In practice, our algorithm has better numerical performance if one of $R_m=n$ and $T_0=n$ is chosen such that the factors become multiples of n, i.e., $R_mT_0\sim n$, as in the deterministic case.

In contrast to the method of BERAHAS et al. [5], which uses the norm condition, our line search does not use the term $c_1 \alpha p^T \tilde{g}(x)$ of the condition (7), since the estimate of the gradient may be inaccurate in the presence of high noise, leading to the failure of the line search algorithm, but $\gamma \alpha^2$. Therefore, we are not interested in obtaining our complexity bound under the norm condition (8). We will only use the estimated gradient to generate some heuristic directions in Section 1 of suppMat.pdf. In all cases, the order of ω in our bounds is the same as in [5], although the nature of the line search algorithms is different. On the other hand, our bounds are obtained with high probability. Therefore, high probability results are more likely to be appropriate and differ from the results of BERAHAS et al. [5], which are valid only in expectation.

The following result generalizes Proposition 1 in [27]. It is shown that if the rth iteration of MLS-basic is unsuccessful, a useful bound for the directional derivative can be found. In this case, no $\gamma \alpha_r^2$ -sufficient gain $(r \in \{1, 2, \dots, R_m\})$ is found along the search directions $\pm p^r$ (good is false when these directions are tried).

Proposition 2 Let $\{z^r\}$ $(r=1,2,\cdots,R_m)$ be the sequence generated by MLS-basic in the (k+1)th iteration of VRBBON-basic. Moreover, suppose that (A1)-(A3) hold and $0 < \gamma < 1$. Then, for all $z^r, p^r \in \mathbb{R}^n$, at least one of the following holds:

(i)
$$\tilde{f}(z_{\text{best}} + \alpha_r p^r) < \tilde{f}(z^r) - \gamma \alpha_r^2$$
,

(ii)
$$\tilde{f}(z_{\text{best}} + \alpha_r p^r) > \tilde{f}(z^r) + \gamma \alpha_r^2$$
 and $\tilde{f}(z_{\text{best}} - \alpha_r p^r) < \tilde{f}(z^r) - \gamma \alpha_r^2$,

(iii)
$$|g(z^r)^T p^r| \le \gamma \alpha_r + 2\omega/\alpha_r + \frac{1}{2}L\alpha_r ||p^r||^2$$
.

Here $z_{
m best}$ is the best point found by MLS-basic in the kth iteration of VRBBON-basic.

Proof (A1) results in

$$\alpha_r g(z^r)^T p^r - \frac{1}{2} L \alpha_r^2 ||p^r||^2 \le f(z_{\text{best}} + \alpha_r p^r) - f(z^r) \le \alpha_r g(z^r)^T p^r + \frac{1}{2} L \alpha_r^2 ||p^r||^2.$$
(11)

We assume that (iii) is violated, so that

$$|g(z^r)^T p^r| > \gamma \alpha_r + 2\omega/\alpha_r + \frac{1}{2} L \alpha_r ||p^r||^2.$$
(12)

We consider the proof in the two cases:

CASE 1. If $g(z^r)^T p^r \leq 0$, then from (2) and (12) we get

$$\tilde{f}(z_{\text{best}} + \alpha_r p^r) - \tilde{f}(z^r) \leq f(z_{\text{best}} + \alpha_r p^r) - f(z^r) + 2\omega
\leq \alpha_r g(z^r)^T p^r + \frac{1}{2} L \alpha_r^2 ||p^r||^2 + 2\omega
= -\alpha_r |g(z^r)^T p^r| + \frac{1}{2} L \alpha_r^2 ||p^r||^2 + 2\omega < -\gamma \alpha_r^2, \quad (13)$$

meaning that good is true if p^r was tried, hence (13) holds.

CASE 2. If $g(z^r)^T p^r \ge 0$, then from (2) and (12) we get

$$\tilde{f}(z_{\text{best}} - \alpha_r p^r) - \tilde{f}(z^r) \leq f(z_{\text{best}} - \alpha_r p^r) - f(z^r) + 2\omega
\leq g(z^r)^T (-\alpha_r p^r) + \frac{1}{2} L \alpha_r^2 ||p^r||^2 + 2\omega
= -\alpha_r |g(z^r)^T p^r| + \frac{1}{2} L \alpha_r^2 ||p^r||^2 + 2\omega < -\gamma \alpha_r^2, \quad (14)$$

meaning that good is true if $-p^{r}$ was tried. Therefore, the second inequality in (ii) holds. By (2), (11), and (12) the first half

$$\tilde{f}(z_{\text{best}} + \alpha_r p^r) - \tilde{f}(z^r) \ge f(z_{\text{best}} + \alpha_r p^r) - f(z^r) - 2\omega$$
$$\ge \alpha_r g(z^r)^T p^r - \frac{1}{2} L \alpha_r^2 ||p^r||^2 - 2\omega > \gamma \alpha_r^2$$

is obtained, meaning that good is false if p^r was tried. Hence the first inequality in (ii) holds.

As discussed earlier, VRBBON-basic has $1 \leq K < \infty$ calls to DS-basic and DS-basic has $1 \leq T_0 < \infty$ calls to MLS-basic. Hence, VRBBON-basic has KT_0 calls to MLS-basic.

As defined in VRBBON-basic, $R_m = \lceil \log_2 \eta^{-1} \rceil$ for a given $0 < \eta < \frac{1}{2}$ is the number of random directions used by MLS-basic. For given $1 \le T_0 < \infty$ and $1 \leq K < \infty$, defined by

$$R_d := T_0 R_m = T_0 \lceil \log_2 \eta^{-1} \rceil \ge \log_2 \eta^{-T_0} \tag{15}$$

is the number of random directions used by DS-basic and defined by

$$R_v := KR_d = KT_0R_m = KT_0\lceil \log_2 \eta^{-1} \rceil \ge \log_2 \eta^{-KT_0}$$
 (16)

is the number of random directions used by VRBBON-basic.

Assuming (A1)-(A4), we find

- for MLS-basic at least one point whose unknown gradient norm is below a constant bound (see (17)) with probability $\geq 1 \eta > \frac{1}{2}$ (see Theorem 3);
- for DS-basic at least one point whose unknown gradient norm is below a constant bound (see (21)) with probability

$$\geq 1 - 2^{-R_d} = 1 - 2^{-T_0 R_m} \geq 1 - \eta^{T_0} \geq 1 - \eta > \frac{1}{2},$$

(see Theorem 4):

• for VRBBON-basic at least one point whose unknown gradient norm is below a constant bound (see (26)) with probability

$$\geq 1 - 2^{-R_v} = 1 - 2^{-KT_0R_m} \geq 1 - \eta^{KT_0} \geq 1 - \eta > \frac{1}{2}$$

(see Theorem 5).

The following result is a generalization of Theorem 1 in [27] for MLS-basic to the noisy case in the (k+1)th iteration of VRBBON-basic. As discussed earlier, MLS-basic uses R_m scaled random directions p^r $(r=1,2,\cdots,R_m)$. If $\alpha_{\min}>0$, in the worst case, it is proved that one of the following holds:

- (i) If at least on iteration $(r' \in \{1, 2, \dots, R_m\})$ of MLS-basic is successful, meaning that good is true when $-p^{r'}$ is tried, a minimum reduction in the inexact function value is found (note that if good is true when $p^{r'}$ is attempted, then $p^{r'}$ is not attempted and this case is not the worst case, so it is a real case).
- (ii) An upper bound on the unknown gradient norm of at least one $z^{r''}$ $(r'' \in \{1, 2, \dots, R_m\})$ of the points generated by the unsuccessful iterations of MLS-basic is found with a given probability arbitrarily close to one. In fact, it is not clear to us which point, since the gradients and Lipschitz constants are not available.

Theorem 3 Let $\{z^r\}$ $(r=1,2,\cdots,R_m)$ be the sequence generated by MLS-basic in the (k+1)th iteration of VRBBON-basic. Assume that (A1)-(A4) hold, nfmax is sufficiently large, $0<\eta<\frac{1}{2},\ 0<\gamma_{\rm rd}<1,\ \gamma_e>1,\ and\ 0<\gamma<1.$ Moreover, let $\overline{L}:=\frac{2\gamma}{\gamma_{\rm rd}}+L\gamma_{\rm rd}$. Then one of the following happens:

- (i) If at least MLS-basic has a successful iteration, $r' \in \{1, 2, \dots, R_m\}$, then it decreases the inexact function value by at least $\gamma \alpha_{r'}^2$.
- (ii) If MLS-basic has no successful iteration, then at least one $z^{r''}$ $(1 \le r'' \le R_m)$ of the points evaluated by the unsuccessful iterations of MLS-basic, with the probability

at least $1 - \eta$, has an unknown gradient $g(z^{r''})$ satisfying

$$||g(z^{r''})||_* \le \sqrt{cn}\Gamma(\delta_k) \quad with \ \Gamma(\delta_k) := \overline{L}\delta_k + \gamma_e^{R_m - 1} \frac{4\omega}{\gamma_{\rm rd}\delta_k}$$
 (17)

for a given $0 < \eta < \frac{1}{2}$. Here c comes from Proposition 1, δ_k is fixed in MLS-basic, independent of r, and is updated outside MLS-basic.

Proof Let $\mathcal{R} := \{1, \dots, R_m\}$. We denote by p^r the rth scaled random search direction, by z^r the rth point, and by $\alpha_r = \gamma_e^{1-r} \delta_k \geq \alpha_{\min}$ the rth step size from (A4).

- (i) Let $r' \in \{1, 2, \dots, R_m\}$. The worst case requires $2R_m+1$ function evaluations and assumes that the r'th iteration of MLS-basic is successful and the other iterations are unsuccessful. In the unsuccessful iterations, two function values are computed along the directions $\pm p^r$ ($r \in \mathcal{R} \setminus \{r'\}$), but in the r'th iteration which is successful, good is false when $p^{r'}$ is attempted and true when $-p^{r'}$ is attempted (as discussed above if good is true when $p^{r'}$ is attempted, then $p^{r'}$ is not attempted and this case is not the worst case, so it is a real case). Therefore, an extrapolation step along $-p^{r'}$ is performed with at most two additional function evaluations and the $\gamma \alpha_{r'}^2$ -sufficient gain. Consequently, (i) is verified.
- (ii) Suppose that $\tilde{f}(z^r)$ does not decrease by more than $\gamma \alpha_r^2$ for all $r \in \mathcal{R}$; all iterations are unsuccessful. Then we define $\Gamma_0(\alpha_r) := \overline{L}\alpha_r + \frac{4\omega}{\gamma_{\rm rd}\alpha_r}$. Since $\Gamma_0(\alpha_r)$ for $\alpha_r > 0$ is a convex function, we obtain for $r \in \mathcal{R}_m$

$$\Gamma_{0}(\alpha_{r}) \leq \max\{\Gamma_{0}(\alpha_{1}), \Gamma_{0}(\alpha_{R})\} < \overline{L}\alpha_{1} + \frac{4\omega}{\gamma_{\mathrm{rd}}\alpha_{R}}$$

$$= \Gamma(\delta_{k}) = \overline{L}\delta_{k} + \gamma_{e}^{R_{m}-1} \frac{4\omega}{\gamma_{\mathrm{rd}}\delta_{k}}, \tag{18}$$

where $\alpha_1 := \max_{r \in \mathcal{R}} \{\alpha_r\} = \delta_k > \alpha_R := \min_{r \in \mathcal{R}} \{\alpha_r\} = \gamma_e^{1 - R_m} \delta_k \text{ since } \gamma_e > 1 \text{ and } R_m \ge 2.$

Then we obtain from Proposition 2 and since $||p^r|| = \gamma_{\rm rd}$ (due to the definition of the scaled random direction in Section 3), for all $r \in \mathcal{R}$,

$$|g(z^r)^T p^r| \le \gamma \alpha_r + 2\omega/\alpha_r + \frac{L}{2}\alpha_r ||p^r||^2 = \gamma \alpha_r + 2\omega/\alpha_r + \frac{L}{2}\gamma_{\rm rd}^2 \alpha_r,$$

so that for all $r \in \mathcal{R}$ and from (18), the inequality

$$||g(z^{r})||_{*} = ||g(z^{r})||_{*}||p^{r}||/\gamma_{\mathrm{rd}} \leq 2\sqrt{cn}|g(z^{r})^{T}p^{r}|/\gamma_{\mathrm{rd}}$$

$$\leq \sqrt{cn}\left(\left(\frac{2\gamma}{\gamma_{\mathrm{rd}}} + L\gamma_{\mathrm{rd}}\right)\alpha_{r} + \frac{4\omega}{\gamma_{\mathrm{rd}}\alpha_{r}}\right) = \sqrt{cn}\Gamma_{0}(\alpha_{r}) < \sqrt{cn}\Gamma(\delta_{k})$$

holds with probability $\frac{1}{2}$ or more according to Proposition 1. In other words,

$$\Pr\left(\|g(z^r)\|_* > \sqrt{cn}\Gamma(\delta_k)\right) < \frac{1}{2}, \text{ for any fixed } r \in \mathcal{R}.$$

Therefore, we find at least one of the gradients $g = g(z^{r''})$ $(r'' \in \mathcal{R})$ such that (17) holds, that is,

$$\Pr\left(\|g\|_* \le \sqrt{cn}\Gamma(\delta_k)\right) = 1 - \prod_{r=1}^{R_m} \Pr\left(\|g(z^r)\|_* > \sqrt{cn}\Gamma(\delta_k)\right) \ge 1 - 2^{-R_m} \ge 1 - \eta,$$

for a given
$$0 < \eta < \frac{1}{2}$$
.

The following result discusses the complexity bound for DS-basic in the (k+1)th iteration of VRBBON-basic. It is proved that either an upper bound on the number of function evaluations is found or an upper bound on the unknown gradient norm of at least one of the points generated by the unsuccessful iterations of DS-basic is found with a given probability arbitrarily close to one in the presence of noise; in fact, it is not clear to us which point, since the gradients and Lipschitz constants are not available.

Theorem 4 Suppose that (A1)-(A4) hold and let $f(x^0)$ be the initial value of f. Moreover, let $\{y^t\}$ $(t=1,2,\cdots,T_0)$ be the sequence generated by DS-basic in the (k+1)th iteration of VRBBON-basic and let $0<\eta<\frac{1}{2},\ 0<\gamma_{\rm rd}<1,\ \gamma_e>1$ and $0<\gamma<1$. Then:

(i) The number of successful iterations of DS-basic is bounded by

$$\overline{\gamma}^{-1} \delta_k^{-2} \Big(f(x^0) - \widehat{f} + 2\omega \Big), \tag{19}$$

where $\overline{\gamma}:=\gamma_e^{2(2-R_m)}\gamma>0$, \widehat{f} is finite by (A1) and (A2) discussed in Section 1.2, and the step size δ_k is fixed, independent of t, and updated outside DS-basic. Moreover, the number of function evaluations of DS-basic is bounded by

$$2R_m T_0 + (2R_m + 1)T_0 \overline{\gamma}^{-1} \delta_k^{-2} \Big(f(x^0) - \widehat{f} + 2\omega \Big).$$
 (20)

(ii) Unsuccessful iterations of DS-basic have at least one point $y^{t'}$ ($1 \le t' \le T_0$), with probability at least $\ge 1 - 2^{-R_d} \ge 1 - \eta > \frac{1}{2}$ for a given $0 < \eta < \frac{1}{2}$, satisfying

$$||g(y^{t'})||_* \le \sqrt{cn}\Gamma(\delta_k),\tag{21}$$

where c and $\Gamma(\delta_k)$ come from Proposition 1 and Theorem 3. Here R_d comes from (15).

Proof (i) S denotes the index set of successful iterations of DS -basic, where each successful iteration is a result of at least one successful iteration of MLS-basic. Let $r' \in \{1, 2, \dots, R_m\}$. As discussed in the proof of Theorem 3(i), in the worst case at least the r'th iteration of MLS-basic is successful that a result of an extrapolation along $-p^{r'}$. We do not know how many times we can extrapolate $\alpha_{r'}$ to γ_e along the fixed direction $-p^{r'}$, but at least once $\alpha_{r'}$ is expanded by γ_e in an extrapolation and

therefore at most $R_m - 1$ times $\alpha_1 = \delta_k$ is reduced by γ_e if we cannot extrapolate along the other scaled random directions and their opposite directions. Therefore, for each $t \in S$, according to the role of updating α_r in lines 19, 36, and 39 of Algorithm 1,

$$\alpha_{r'} \ge \gamma_e \delta_k / \gamma_e^{R_m - 1} = \gamma_e^{2 - R_m} \delta_k$$

in the (k+1)th iteration of VRBBON-basic. Put $\overline{\gamma}:=\gamma_e^{2(2-R_m)}\gamma>0$. We now find an upper bound on the number of successful iterations and the corresponding function evaluations of DS-basic. For all $t\in S$ in the (k+1)th iteration of VRBBON-basic, we have

$$\tilde{f}(y^{t+1}) - \tilde{f}(y^t) = \tilde{f}(z^{\hat{r}}) - \tilde{f}(z_{\text{best}}) \le -\gamma \alpha_{r'}^2 \le -\overline{\gamma} \delta_k^2,$$

recursively resulting in $\tilde{f}(y^{t+1}) \leq \tilde{f}(x^0) - \overline{\gamma}\delta_k^2 \sum_{t \in S} 1 = \tilde{f}(x^0) - \overline{\gamma}\delta_k^2 |S|$. From (2) we

conclude that

$$|S| \leq \overline{\gamma}^{-1} \delta_k^{-2} \Big(\widetilde{f}(x^0) - \widetilde{f}(y^{t+1}) \Big) \leq \overline{\gamma}^{-1} \delta_k^{-2} \Big(f(x^0) - \widehat{f} + 2\omega \Big).$$

Therefore, (19) is valid. The step size δ_k is fixed, independent of t, and updated outside DS-basic. As mentioned earlier, MLS-basic requires at most $2R_m+1$ function evaluations in the worst case (using R_m scaled random directions and R_m corresponding opposite directions, all iterations of MLS-basic are unsuccessful; however, if the r'th iteration is successful, then good is false when $p^{r'}$ is attempted and true when $-p^{r'}$ is attempted; a sufficient gain along the last opposite direction $-p^{r'}$ is found. Therefore, an extrapolation with at most two function evaluations is attempted. Therefore, the successful iterations of DS-basic use at most

$$(2R_m+1)\overline{\gamma}^{-1}\delta_k^{-2}\left(f(x^0)-\widehat{f}+2\omega\right)$$

function evaluations.

U denotes the index set of unsuccessful iterations of DS-basic. Since $T_0 = |U| + |S|$ and MLS-basic uses $2R_m$ function evaluations for each unsuccessful iteration, we conclude that the unsuccessful iterations of DS-basic use at most $2R_m|U| \leq 2R_mT_0$ function evaluations. Consequently, the number of function evaluations of DS-basic is bounded by (20).

(ii) In this case, the unsuccessful iterations of DS-basic generate the sequence y^t $(t=1,\cdots,T_0)$, resulting in, that for at least one $y^{t'}$ $(1 \le t' \le T_0)$ of the evaluated points, with probability $\ge 1 - 2^{-R_d} = 1 - 2^{-T_0R_m} \ge 1 - \eta^{T_0} \ge 1 - \eta$, $||g(y^{t'})||_* \le \sqrt{cn}\Gamma(\delta_k)$ holds for a given $0 < \eta < \frac{1}{2}$. As mentioned in (i), the step size δ_k is fixed, independent of t; hence the bound $\sqrt{cn}\Gamma(\delta_k)$ is fixed for DS-basic.

The objective function f is convex $(\sigma = 0)$ if the condition

$$f(y) \ge f(x) + g(x)^T (y - x) + \frac{1}{2} \sigma ||y - x|| \text{ for } x, y \in \mathbb{R}^n$$
 (22)

holds and is strongly convex ($\sigma > 0$) if (22) holds.

It is proved that an upper bound for the unknown gradient norm of at least one of points generated by the unsuccessful iterations of VRBBON-basic is found for all cases with a given probability arbitrarily close to one in the presence of noise.

Theorem 5 Let $\{x^k\}$ $(k=1,2,\cdots)$ be the sequence generated by VRBBON-basic. Assume that (A1)-(A4) hold and $\delta_{\max}>0,\ Q>1,\ 0<\gamma_{\rm rd}<1,\ \gamma_e>1,\ 0<\gamma<1,$

$$\delta_{\min} := \Theta(\sqrt{\omega}) \tag{23}$$

and nfmax is sufficiently large. Then

$$\delta_{\ell} = Q^{1-\ell} \delta_{\text{max}} \quad \text{for } \ell > 1 \tag{24}$$

and VRBBON-basic terminates after at most

$$K := 1 + \left\lfloor \frac{\log(\delta_{\max}/\delta_{\min})}{\log Q} \right\rfloor = \mathcal{O}(\log \omega^{-1/2})$$
 (25)

unsuccessful iterations. Then, for a given $0 < \eta < \frac{1}{2}$, VRBBON-basic finds at least one point $x^{\ell'}$ with probability at least $1 - 2^{-R_v} \ge 1 - \eta$ satisfying (i) in the nonconvex case the condition

$$||g(x^{\ell'})||_* = \mathcal{O}(\sqrt{n\omega}); \tag{26}$$

(ii) in the convex case the condition (26) and

$$f(x^{\ell'}) - \widehat{f} = \mathcal{O}(r_0 \sqrt{n\omega}), \tag{27}$$

where r_0 is given by

$$r_0 := \sup \left\{ \|x - \widehat{x}\| \mid x \in \mathbb{R}^n, \ f(x) \le f(x^0) \right\} < \infty;$$
 (28)

(iii) in the strongly convex case the condition (26),

$$f(x^{\ell'}) - \widehat{f} = \frac{\mathcal{O}(n\omega)}{2\sigma}, \quad and \quad ||x^{\ell'} - \widehat{x}|| = \frac{\mathcal{O}(\sqrt{n\omega})}{\sigma}.$$
 (29)

Here \hat{f} is finite by (A1) and (A2) discussed in Section 1.2 and R_v comes from (16).

Proof (i) Since VRBBON-basic has K unsuccessful iterations, from calls to DS-basic and Theorem 4(ii), the condition

$$||g(x^{\ell'})||_* \le \sqrt{cn} \min_{\ell=0:K} \Gamma(\delta_{\ell}), \tag{30}$$

holds for at least one $x^{\ell'}$ of the evaluated points with probability

$$\geq 1 - 2^{-R_v} = 1 - 2^{-T_0 K R_m} \geq 1 - \eta^{T_0 K} \geq 1 - \eta > \frac{1}{2}$$

for a given $0 < \eta < \frac{1}{2}$. By (25), we have $\delta_K = Q^{1-K}\delta_{\max} \le \delta_{\min}$. Then (23)–(25) yield

$$\Gamma(\delta_K) \, = \, \overline{L}\delta_K + \gamma_e^{R_m - 1} \frac{4\omega}{\gamma_{\rm rd}\delta_K}$$

$$= \overline{L}Q^{1-K}\delta_{\max} + \gamma_e^{R_m - 1}Q^{K-1}\frac{4\omega}{\gamma_{\rm rd}\delta_{\max}} = \mathcal{O}(\sqrt{\omega}),$$

whose application in (30) leads to (26). Here \overline{L} comes from Theorem 3.

(ii) The convexity of f leads to

$$\widehat{f} \ge f_{\ell} + g(x^{\ell})^T (\widehat{x} - x^{\ell})$$
 for all $\ell \ge 0$.

(i) leads to the fact that for at least one $x^{\ell'}$ of the evaluated points with probability $\geq 1 - 2^{-R_v} > \frac{1}{2}$ the condition

$$f_{\ell'} - \widehat{f} \le g(x^{\ell'})^T (x^{\ell'} - \widehat{x}) \le \|g(x^{\ell'})\|_* \|x^{\ell'} - \widehat{x}\| = \mathcal{O}(r_0 \sqrt{n\omega})$$

holds for a given $0 < \eta < \frac{1}{2}$.

(iii) If x is assumed to be fixed, the right-hand side of (22) is a convex quadratic function with respect to y whose gradient in the components vanishes at $y_i = x_i - s_i \sigma^{-1} g_i(x)$ for $i = 1, \dots, n$, leading to $f(y) \geq f(x) - \frac{1}{2\sigma} \|g(x)\|_*^2$. As mentioned earlier, $s \in \mathbb{R}^n$ is a scaling vector here. By applying (26) in this inequality, we obtain at least for one $x^{\ell'}$ of the evaluated points with probability $\geq 1 - 2^{-R_v} > \frac{1}{2\sigma}$

$$f_{\ell'} - \widehat{f} \leq \frac{1}{2\sigma} \|g(x^{\ell'})\|_*^2 = \frac{\mathcal{O}(n\omega)}{2\sigma} \text{ for } \ell' \geq 0 \text{ and a given } 0 < \eta < \frac{1}{2}.$$

Substituting x for \widehat{x} and y for $x^{\ell'}$ into (22), we get $f_{\ell'} \ge f(\widehat{x}) + \frac{\sigma}{2} ||x^{\ell'} - \widehat{x}||^2$ such that (i) leads to the fact that for at least one $x^{\ell'}$ of the evaluated points with probability

(i) leads to the fact that for at least one x^{ϵ} of the evaluated points with probability $\geq 1 - 2^{-R_v} > \frac{1}{2}$

$$\|x^{\ell'} - \widehat{x}\|^2 \le \frac{2}{\sigma} (f_{\ell'} - \widehat{f}) \le \frac{1}{\sigma^2} \|g(x^{\ell'})\|_*^2 = \frac{\mathcal{O}(n\omega)}{\sigma^2}$$

holds for a given $0 < \eta < \frac{1}{2}$.

Compared to the results discussed in Section 1.2, the order of ω in the bound (26) is the same as that in (5) and (6). The conditions (27) and (29) are the same as those of BERAHAS et al. [5], except that they are satisfied with high probability.

The following result discusses the complexity bound for VRBBON-basic for all cases. It is proved that an upper bound on the number of function evaluations used by VRBBON-basic is found with a given probability arbitrarily close to one in the presence of noise.

Theorem 6 Let $\{x^k\}$ $(k=1,2,\cdots)$ be the sequence generated by VRBBON-basic. Under the assumptions of Theorem 5, VRBBON-basic terminates after at most

- (i) $\mathcal{O}(R_m T_0 \omega^{-1})$ function evaluations in the nonconvex case,
- (ii) $\mathcal{O}(\sqrt{n}R_mT_0\omega^{-1/2})$ function evaluations in the convex case,
- (iii) $\mathcal{O}(nR_mT_0\log\omega^{-1})$ function evaluations in the strongly convex case.

Proof Denote by N_K the number of function evaluations for the termination of VRBBON-basic, put $N_0 := 1$, and denote $f_\ell = f(x^\ell)$. Here K comes from (25). In worst case, we terminate VRBBON-basic after at most K unsuccessful iterations from calls to DS-basic, with K points satisfying (21), and at least one point satisfying (26). Since the gradient and Lipschitz constants are unknown, these points are unknown. As a consequence of this termination, we have $\delta_\ell = Q^{1-\ell}\delta_{\max} \leq \delta_{\min}$ for $\ell \geq K$ and

$$\delta_{\ell} \ge \delta_{\min} \text{ for } \ell \in \mathcal{B} := \{1, \cdots, K\}.$$
 (31)

The condition (31) is used in the proof of (ii) and (iii).

(i) We conclude from (20) and (24)–(25) that

$$N_{K} \leq 1 + \sum_{\ell=1}^{K} \left(2T_{0} + (2R_{m} + 1)T_{0}\overline{\gamma}^{-1}\delta_{\ell}^{-2}(f(x^{0}) - \widehat{f} + 2\omega) \right)$$

$$= 1 + 2R_{m}T_{0}K + (2R_{m} + 1)T_{0}\overline{\gamma}^{-1}\left(f(x^{0}) - \widehat{f} + 2\omega\right)\sum_{\ell=1}^{K}\delta_{\ell}^{-2}$$

$$= 1 + 2R_{m}T_{0}K + (2R_{m} + 1)T_{0}\overline{\gamma}^{-1}\delta_{\max}^{-2}\left(f(x^{0}) - \widehat{f} + 2\omega\right)\sum_{\ell=1}^{K}Q^{2\ell-2}$$

$$= 1 + 2R_{m}T_{0}K + (2R_{m} + 1)T_{0}\overline{\gamma}^{-1}\delta_{\max}^{-2}\left(f(x^{0}) - \widehat{f} + 2\omega\right)\frac{Q^{2K} - 1}{Q^{2} - 1}.$$

Here $\overline{\gamma}$ comes from Theorem 4 and for a given $0 < \eta < \frac{1}{2} R_m = \lceil \log_2 \eta^{-1} \rceil \geq 2$ comes from Algorithm 1. In this case, $R_m Q^{2K}$ dominates the other terms $(R_m K, R_m \omega Q^{2K}, Q^{2K}, \omega Q^{2K})$, resulting in

$$N_K = \mathcal{O}(R_m T_0 \omega^{-1}).$$

(ii) From (A1) and (A2), r_0 is finite. The convexity of f results in

$$\widehat{f} \ge f_{\ell} + g(x^{\ell})^T (\widehat{x} - x^{\ell})$$
 for all $\ell \ge 0$.

By Theorem 5, for a given $0 < \eta < \frac{1}{2}$, we get with probability $\geq 1 - 2^{-R_v} \geq 1 - \eta > \frac{1}{2}$

$$f_{\ell} - f_{\ell+1} \le f_{\ell} - \widehat{f} \le g(x^{\ell})^T (x^{\ell} - \widehat{x}) \le ||g(x^{\ell})||_* ||x^{\ell} - \widehat{x}||$$
 (32)

$$\leq r_0 \sqrt{cn} \left(\overline{L} \delta_{\ell} + \gamma_e^{R_m - 1} \frac{4\omega}{\gamma_{\rm rd} \delta_{\ell}} \right) \text{ for } \ell \in \mathcal{B}.$$
 (33)

Here \overline{L} comes from Theorem 3. We consider the following two cases:

CASE 1. The first term $\overline{L}\delta_{\ell}$ in (33) dominates the second term. Then we have

$$f_{\ell} - f_{\ell+1} = \mathcal{O}(\sqrt{n}\delta_{\ell}) \quad \text{for } \ell \in \mathcal{B} .$$
 (34)

Then we define $\mathcal{B}_1 := \{\ell \in \mathcal{B} \mid (34) \text{ holds}\}.$

Case 2. The second term $4\gamma_e^{R_m-1}\omega/(\gamma_{\rm rd}\delta_\ell)$ in (33) dominates the first term. Then we conclude from (31) that

$$f_{\ell} - f_{\ell+1} = \mathcal{O}(\sqrt{n}(\omega/\delta_{\ell})) = \mathcal{O}(\sqrt{n}(\omega/\delta_{\min})) = \mathcal{O}(\sqrt{n\omega}) \text{ for } \ell \in \mathcal{B}.$$
 (35)

Then we define $\mathcal{B}_2 = \{\ell \in \mathcal{B} \mid (35) \text{ holds}\}.$

Then we conclude from (24), (23), and (25) that with probability $\geq 1 - 2^{-R_v} > \frac{1}{2}$

$$\begin{split} \sum_{\ell \in \mathcal{B}} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\delta_{\ell}^2} &= \sum_{\ell \in \mathcal{B}_1} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}_2} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\gamma \delta_{\ell}^2} \\ &\leq \sum_{\ell \in \mathcal{B}_1} \frac{f_{\ell} - f_{\ell+1} + 2\omega}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}_2} \frac{f_{\ell} - f_{\ell+1} + 2\omega}{\delta_{\ell}^2} \\ &\leq \sum_{\ell \in \mathcal{B}_1} \frac{\mathcal{O}(\sqrt{n}\delta_{\ell}) + 2\omega}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}_2} \frac{\mathcal{O}(\sqrt{n\omega}) + 2\omega}{\delta_{\ell}^2} \\ &\leq \sum_{\ell \in \mathcal{B}} \frac{\mathcal{O}(\sqrt{n}\delta_{\ell}) + 2\omega}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}} \frac{\mathcal{O}(\sqrt{n\omega}) + 2\omega}{\delta_{\ell}^2} \\ &= \mathcal{O}(\sqrt{n}) \sum_{\ell \in \mathcal{B}} \delta_{\ell}^{-1} + \mathcal{O}(\sqrt{n\omega}) \sum_{\ell \in \mathcal{B}} \delta_{\ell}^{-2} + 4\omega \sum_{\ell \in \mathcal{B}} \delta_{\ell}^{-2} \\ &= \mathcal{O}(\sqrt{n}) \sum_{\ell \in \mathcal{B}} Q^{\ell-1} + \mathcal{O}(\sqrt{n\omega}) \sum_{\ell \in \mathcal{B}} Q^{2\ell-2} + 4\omega \sum_{\ell \in \mathcal{B}} Q^{2\ell-2} \\ &= \mathcal{O}(\sqrt{n}Q^K) + \mathcal{O}(\sqrt{n\omega}Q^{2K}) + \omega \mathcal{O}(Q^{2K}) \\ &= \mathcal{O}(\sqrt{n}\omega^{-1/2}) + \mathcal{O}(\sqrt{n\omega}\omega^{-1}) + \omega \mathcal{O}(\omega^{-1}) \\ &= \mathcal{O}(\sqrt{n}\omega^{-1/2}) + \mathcal{O}(\sqrt{n\omega}\omega^{-1/2}) + \mathcal{O}(n) = \mathcal{O}(\sqrt{n}\omega^{-1/2}), \end{split}$$

holds for a given $0 < \eta < \frac{1}{2}$, so that by (i) and $R_m = \lceil \log_2 \eta^{-1} \rceil \ge 2$

$$N_K \le 1 + (2R_m + 1)T_0 \sum_{\ell \in \mathcal{B}} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\gamma \delta_{\ell}^2} = \mathcal{O}\left(\sqrt{n}R_m T_0 \omega^{-1/2}\right)$$

holds with probability $\geq 1 - 2^{-R_v} \geq 1 - \eta > \frac{1}{2}$ for a given $0 < \eta < \frac{1}{2}$.

(iii) When x is assumed to be fixed, the right hand side of (22) is a convex quadratic function in terms of y whose gradient in the components vanishes at $y_i = x_i - s_i \sigma^{-1} g_i(x)$ for $i = 1, \dots, n$, resulting in $f(y) \geq f(x) - \frac{1}{2\sigma} \|g(x)\|_*^2$. Here as mentioned earlier $s \in \mathbb{R}^n$ is a scaling vector. By applying (26) in this inequality, for a given $0 < \eta < \frac{1}{2}$, we get with probability $\geq 1 - 2^{-R_v} \geq 1 - \eta > \frac{1}{2}$

$$|f_{\ell} - f_{\ell+1}| \le |f_{\ell} - \widehat{f}| \le \frac{1}{2\sigma} ||g(x^{\ell})||_*^2 \le \frac{cn}{2\sigma} \left(\overline{L} \delta_{\ell} + \gamma_e^{R_m - 1} \frac{4\omega}{\gamma_{\rm rd} \delta_{\ell}} \right)^2 \text{ for } \ell \in \mathcal{B}.$$

Here \overline{L} comes from Theorem 3. We consider the following two cases:

Case 1. The first term $\overline{L}\delta_{\ell}$ in (36) dominates the second term. Then we have

$$f_{\ell} - f_{\ell+1} = \mathcal{O}(n\delta_{\ell}^2) \quad \text{for } \ell \in \mathcal{B}$$
 (36)

and denote $\mathcal{B}_1 := \{\ell \in \mathcal{B} \mid (36) \text{ holds}\}.$

CASE 2. The second term $4\gamma_e^{R_m-1}\omega/(\gamma_{\rm rd}\delta_\ell)$ in (36) dominates the first term. Then we conclude from (31) that

$$f_{\ell} - f_{\ell+1} = \mathcal{O}\left(n(\omega/\delta_{\ell})^2\right) = \mathcal{O}\left(n(\omega/\delta_{\min})^2\right) = \mathcal{O}(n\omega) \text{ for } \ell \in \mathcal{B}$$
 (37)

and denote $\mathcal{B}_2 = \{\ell \in \mathcal{B} \mid (37) \text{ holds}\}.$

Then for a given $0 < \eta < \frac{1}{2}$ we conclude from (23)–(25) that with probability $\geq 1 - 2^{-R_v} \geq 1 - \eta > \frac{1}{2}$

$$\begin{split} \sum_{\ell \in \mathcal{B}} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\delta_{\ell}^2} &= \sum_{\ell \in \mathcal{B}_1} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}_2} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\delta_{\ell}^2} \\ &\leq \sum_{\ell \in \mathcal{B}_1} \frac{f_{\ell} - f_{\ell+1} + 2\omega}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}_2} \frac{f_{\ell} - f_{\ell+1} + 2\omega}{\delta_{\ell}^2} \\ &\leq \sum_{\ell \in \mathcal{B}_1} \frac{\mathcal{O}(n\delta_{\ell}^2) + 2\omega}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}_2} \frac{\mathcal{O}(n\omega) + 2\omega}{\delta_{\ell}^2} \\ &\leq \sum_{\ell \in \mathcal{B}} \frac{\mathcal{O}(n\delta_{\ell}^2) + 2\omega}{\delta_{\ell}^2} + \sum_{\ell \in \mathcal{B}} \frac{\mathcal{O}(n\omega) + 2\omega}{\delta_{\ell}^2} \\ &= \mathcal{O}(n)K + \mathcal{O}(n\omega) \sum_{\ell \in \mathcal{B}} \delta_{\ell}^{-2} + 4\omega \sum_{\ell \in \mathcal{B}} \delta_{\ell}^{-2} \\ &= \mathcal{O}(n)K + \mathcal{O}(n\omega) \sum_{\ell \in \mathcal{B}} Q^{2\ell-2} + 4\omega \sum_{\ell \in \mathcal{B}} Q^{2\ell-2} \\ &= \mathcal{O}(n)K + \mathcal{O}(n\omega)\mathcal{O}(Q^{2K}) + \omega\mathcal{O}(Q^{2K}) \\ &= \mathcal{O}(n\log \omega^{-1}) + \mathcal{O}(n\omega\omega^{-1}) + \omega\mathcal{O}(\omega^{-1}) = \mathcal{O}(n\log \omega^{-1}) \end{split}$$

so that by (i) and since $R_m = \lceil \log_2 \eta^{-1} \rceil \ge 2$,

$$N_K \le 1 + (2R_m + 1)T_0 \sum_{\ell \in \mathcal{B}} \frac{\tilde{f}_{\ell} - \tilde{f}_{\ell+1}}{\gamma \delta_{\ell}^2} = \mathcal{O}(nR_m T_0 \log(\omega^{-1}))$$

holds with probability $\geq 1 - 2^{-R_v} \geq 1 - \eta > \frac{1}{2}$ for a given $0 < \eta < \frac{1}{2}$.

Compared to the results discussed in Section 1.2, the order ω of our complexity bounds is the same as that of Berahas et al. [5] which is valid in expectation.

If $R_mT_0 \sim n$, then the factors of our bounds in the nonconvex, convex, and strongly convex regions will be large by a factor n, as in the deterministic case. We have shown numerically in Section 3 of suppMat.pdf that the efficiency and robustness of an improved version of VRBBON-basic with $R_mT_0 \sim 1$ are reduced, although our factors are better by a factor n than in the deterministic case (see Bandeira et al. [3] and Kimiaei & Neumaier [27]). When $R_mT_0 \sim n$ is satisfied, the efficiency and robustness of an improved version of VRBBON-basic are actually increased.

In the next section, we discuss that the complexity results are not satisfied if scaled random directions are not used and are otherwise valid. In fact, using scaled random directions guarantees our complexity results, and other types of directions (Section 1 of suppMat.pdf) can be used to increase the efficiency and robustness of an improved version of VRBBON-basic.

6 VRBBON, an improved version of VRBBON-basic

This section discusses some implementation details, tuning parameters of VRBBON-baisc, and under which conditions the complexity results for VRBBON can be guaranteed.

The values of tuning parameters of VRBBON-baisc are Q=1.5, $\gamma_{\rm rd}=10^{-30}$, $\delta_{\rm min}=0$, $\delta_{\rm max}=1$, $\gamma=10^{-6}$, $\gamma_e=3$, $R_m=n$, and $T_0=5$. The values of tuning parameters of VRBBON are chosen in Table 1 of suppMat.pdf after VRBBON is ennriched by many practical enhancements discussed in Section 1 of suppMat.pdf.

Since the three tuning parameters $R_m \geq 2$ (number of scaled random directions in MLS), $C \geq 2$ (number of random approximate coordinate directions), and $T_0 \geq 1$ (number of calls to MLS by DS) affect the factors of our complexity bounds, and since the model-based case (model = 1) is preferable to the model-free case (model = 0) in the presence of noise, we perform a testing and tuning for these tuning parameters in Section 3 of suppMat.pdf. Based on our findings, other tuning parameters were fixed as they did not change the efficiency and robustness of our solver.

The variable comBound takes values of 0,1,2 and is a tuning parameter for considering three cases for the complexity results of VRBBON. Accordingly, we discuss the conditions under which complexity results can be found for VRBBON: Case 1 (comBound = 0). In this case, random approximate coordinate directions are used and random scaled directions are ignored. Other proposed directions and heuristic techniques are also used. In this case, Proposition 1 may not be valid and no complexity result is found for VRBBON.

CASE 2 (comBound = 1). Both random scaled directions and random approximate coordinate directions are used. Other proposed directions and heuristic techniques are also used. In this case, the order of complexity bounds does not change for all cases after heuristic improvements are used, but only their factors become larger

CASE 3 (comBound = 2). In this case, random scaled directions are used and random approximate coordinate directions are ignored. Other proposed directions and heuristic techniques are also used. The order of complexity bounds does not change for all cases after applying the heuristic improvements, only their factors become larger.

In Case 2 and Case 3, Theorem 3, Theorem 4, and Theorem 6 remain valid with the following modifications:

• In Theorem 3(i), R_m (number of scaled random steps in each MLS) must be replaced by T (number of all trial steps), and Theorem 3(ii) remains valid with probability $\geq 1 - 2^{-R_v} \geq 1 - \eta > \frac{1}{2}$ for a given $0 < \eta < \frac{1}{2}$.

• In Theorem 4(i), the number of function evaluations of DS is bounded by

$$(2R_m + 2C + 4)T_0 + (2R_m + 2C + 5)T_0\overline{\gamma}^{-1}\delta_k^{-2}(f(x^0) - \hat{f} + 2\omega)$$

and

$$(2R_m+4)T_0 + (2R_m+5)T_0\overline{\gamma}^{-1}\delta_k^{-2}(f(x^0)-\widehat{f}+2\omega)$$

in Case 2 and Case 3, respectively. As mentioned earlier, the step size δ_k is fixed, independent of t, and updated outside DS. We have described at the end of Section 1.8 of suppMat.pdf how to obtain the factors of the above two bounds. Theorem 5(ii) remains valid.

• In the proof of Theorem 6, $2R_mT_0$ and $(2R_m+1)T_0$ must be replaced by $(2R_m+2C+4)T_0$ and $(2R_m+2C+5)T_0$, respectively, in CASE 2 and by $(2R_m+4)T_0$ and $(2R_m+5)T_0$, respectively, in CASE 3.

7 Numerical results

In this section, we describe how the test problems are selected. Performance measures are then defined to determine which solvers are robust and efficient for small to large scale problems. We then compare our solver with state-of-the-art solvers for low to high dimensional problems (results are averaged over five runs). Finally, we make a recommendation as to which solvers are robust and efficient based on dimension and noise level.

Details of the solvers compared can be found in Section 2 of suppMat.pdf. However, a list of solvers compared are VRBBO by Kimiaei & Neumaier [27], SNOBFIT by Huyer & Neumaier [24], GRID by Elster & Neumaier [15], UOBYQA and NEWUOA by Powell [35, 36], BFO by Porcelli & Toint [34], DSPFD by Gratton et al. [17], MCS by Huyer & Neumaier [23], BCDFO by Gratton et al. [19], SDBOX by Lucidi & Sciandrone [30], CMAES by Auger & Hansen [2], LMMAES by Loshchilov et al. [29], fMAES by Beyer [6], and BiPopMAES by Beyer & Sendhoff [7]. Moreover, subUOBYQA, subNeWUOA, and subNMSMAX are respectively UOBYQA, NEWUOA, and NMSMAX in a random subspace to handle problems in medium and high dimensions.

7.1 Test problems

For our numerical results, we used 549 unconstrained CUTEst test problems from the collection of GOULD et al. [16]. To prepare these results, the test environment of KIMIAEI & NEUMAIER [26] was used.

The starting point. As in [27], we choose the starting point $x^0 := 0$ and shift the arguments by

$$\xi_i := (-1)^{i-1} \frac{2}{2+i}$$
, for all $i = 1, \dots, n$,

to avoid a solver guessing the solution of toy problems with a simple solution (e.g., all zeros or all ones) – there are quite a few of these in the CUTEst library. That is, the initial point is chosen by $x^0 := \xi$ and the initial inexact function value is $\tilde{f}_0 := \tilde{f}(x^0)$ while the other inexact function values are computed by $\tilde{f}_\ell := \tilde{f}(x^\ell + \xi)$ for all $\ell \geq 0$. In fact, this choice increases the difficulty of the problems, see Section 7.3.1.

Type of noise. In the numerical results reported here, uniform random noise is used, which is consistent with the assumption (A3). The function values are calculated by $\tilde{f} = f + (2*\text{rand}-1)\omega$, where f is the true function value and $\omega \geq 0$ is a noise level whose size identifies the difficulty of the noisy problems. Here rand stands for the uniformly distributed random number.

7.2 Performance measures

Two important tools for figuring out which solver is robust and efficient are the data profile of Moré & Wild [32] and the performance profile of Dolan & Moré [14], respectively. S denotes the list of compared solvers and P denotes the list of problems. The fraction of problems that the solver s can solve with κ groups of $n_p + 1$ function evaluations is the data profile of the solver s, i.e.,

$$\delta_s(\kappa) := \frac{1}{|\mathcal{P}|} \left| \left\{ p \in \mathcal{P} \mid cr_{p,s} := \frac{c_{p,s}}{n_p + 1} \le \kappa \right\} \right|. \tag{38}$$

Here n_p is the dimension of the problem p, $c_{p,s}$ is the cost measure of the solver s to solve the problem p and $cr_{p,s}$ is the cost ratio of the solver s to solve the problem p. The fraction of problems that the performance ratio $pr_{p,s}$ is at most τ is the performance profile of the solver s, i.e.,

$$\rho_s(\tau) := \frac{1}{|\mathcal{P}|} \left| \left\{ p \in \mathcal{P} \mid pr_{p,s} := \frac{c_{p,s}}{\min(c_{p,\overline{s}} \mid \overline{s} \in S)} \le \tau \right\} \right|. \tag{39}$$

Note that $\rho_s(1)$ is the fraction of problems that the solver s wins compared to the other solvers, while $\rho_s(\tau)$ ($\delta_s(\kappa)$) is the fraction of problems for sufficiently large τ (κ) that the solver s can solve. The data and performance profiles are based on the problem scales, but not on the noise levels. The other two plots are based on the noise levels. These four plots are used to identify the behaviour of the compared solvers with respect to problem scales and noise levels.

Efficiency. The efficiency $e_{p,s}$ of the solver s to solve the problem p is the inverse of the performance ratio $pr_{p,s}$. Efficiency measures the ability of a solver $s \in \mathcal{S}$ relative to an ideal solver. The number of function evaluations is taken as a suitable cost measure, and the efficiency relative to this measure is called the **nf** efficiency. The robustness of a solver counts the number of problems it solves.

Other plots based on the noise level. To see the behaviour of the compared solvers in the presence of low to high noise, we plot the number of problems solved and the efficiency versus the noise level.

Measure for the convergence speed. The quotients

$$q_s := (f_s - f_{\text{opt}})/(f_0 - f_{\text{opt}}) \quad \text{for } s \in \mathcal{S}$$
(40)

are measures to identify the convergence speed of the solver s to reach a minimum of the smooth true function f. These quotients are not available in real applications. Here

- f_s is the best function value found by the solver s,
- f_0 is the function value at the starting point (common for all solvers),
- f_{opt} is the function value at the best known point (in most cases a global minimizer or at least a better local minimizer) found by running a sequence of gradient-based and local/global gradient free solvers; see Appendix B in [27].

Maximum budgets and stopping tests.

We consider a problem solved by the solver s if $q_s \leq \varepsilon$ and neither the maximum number nfmax of function evaluations nor the maximum allowed time secmax in seconds was reached, and unsolved otherwise. ε , secmax and nfmax are chosen so that the best solver can solve at least half of the problems. They depend on the dimension and the noise level because increasing the noise level and dimension extremely increases the difficulty of the problems. Therefore, ε is chosen slightly larger for problems in medium and high dimensions than for problems in low dimensions. The following choices were found valuable:

$$\begin{split} \mathtt{secmax} &= \begin{cases} 180 & \text{if } 1 \leq n \leq 300, \\ 420 & \text{if } 301 \leq n \leq 5000, \end{cases} \\ \mathtt{nfmax} &= \begin{cases} 2n^2 + 1000n + 5000 & \text{if } 1 \leq n \leq 300, \\ 500n & \text{if } 301 \leq n \leq 5000 \end{cases} \end{split}$$

and

$$\varepsilon := \begin{cases} 10^{-3} & \text{if } \omega \in \{10^{-4}, 10^{-3}\} \text{ and } n \in [1, 30], \\ 10^{-2} & \text{if } \omega \in \{0.1, 0.9\} \text{ and } n \in [1, 30], \\ 10^{-3} & \text{if } \omega = 10^{-4} \text{ and } n \in [31, 300], \\ 0.05 & \text{if } \omega \in \{0.1, 0.01, 0.001\} \text{ and } n \in [31, 300], \\ 0.05 & \text{if } \omega \in \{10^{-5}, 10^{-4}, 10^{-3}\} \text{ and } n \in [301, 5000]. \end{cases}$$

7.3 Comparison with the other solvers

This section compares the default version of VRBBON with the other solvers for problems in low to high dimensions. In each figure, we display only the best five solvers, but the best four solvers in high dimensions.

7.3.1 Small scale: $1 < n \le 30$

For the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-1}, 0.9\}$ and small scale problems $(1 < n \le 30)$, this section contains a comparison between VRBBON and well-known model-based solvers (UOBYQA, NEWUOA, BCDFO, GRID, and SNOBFIT), direct search solvers (NMSMAX, BFO, MCS, DSPFD), line search solvers (VRBBO, SDBOX, FMINUNC), and matrix adaptation evolution solvers (CMAES, fMAES, BiPopMAES, LMMAES). Moreover, a comparison is given between standard and shifted initial points.

To compare our algorithm with the well-known model-based and direct search solvers, Figure 1 shows the cumulative (over all noise levels used) performance and data profiles in its subfigures in terms of the number of function evaluations and the other two plots show (the nf efficiency versus the noise level ω and the number of solved problems versus the noise level ω). From the subfigures of Figure 1, NEWUOA is more efficient than the well-known model-based solvers and VRBBON, while UOBYQA is more robust than others. On the other hand, VRBBON, the second robust solver, is more efficient than SNOBFIT and GRID and less efficient than others. Moreover, VRBBON and NMSMAX are more robust and efficient than the well-known direct search solvers. In fact, VRBBON is more robust than NMSMAX, while NMSMAX is more efficient than VRBBON.

To compare our algorithm with the well-known line search and matrix adaptation evolution solvers, Figure 2 shows in its subfigures, the cumulative (over all noise levels used) performance and data profiles in terms of the number of function evaluations and the other two plots show in terms of the noise levels (the nf efficiency versus the noise level ω and the number of solved problems versus the noise level ω). From the subfigures of Figure 2, we conclude that VRBBON is more robust and efficient than the known line search solvers, while VRBBON is more robust and efficient than the known matrix adaptation evolution solvers at low noise and fMAES is more robust and efficient than others

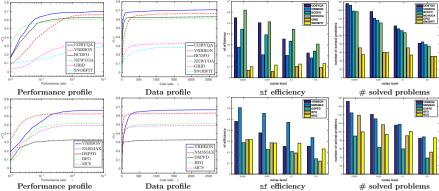

Fig. 1: Comparison between VRBBON and model-based solvers (first row) and direct search solvers (second row) for the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-1}, 0.9\}$ and small dimensions $1 < n \le 30$. Data profile $\delta(\kappa)$ in dependence of a bound κ on the cost ratio, see (38) while performance profile $\rho(\tau)$ in dependence of a bound τ on the performance ratio, see (39). Problems solved by no solver are ignored. Here '# solved problems' counts the number of solved problems.

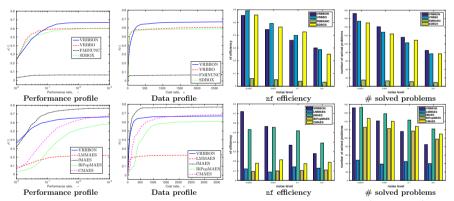

Fig. 2: Comparison between VRBBON and line search solvers (first row) and matrix adaptation evolution solvers solvers (second row). Details as in Figure 1.

at high noise. At low to high noise, VRBBON is slightly more efficient than the known matrix adaptation evolution solvers, while fMAES is more robust than others.

Since our solver is model-based and line search-based, we now provides two comparisons between VRBBON and the best model-based (UOBYQA, NEWUOA, and BCDFO) and line search solvers (SDBOX and VRBBO) with the shifted and initial starting points for small scale problems.

If the default starting points are used, we conclude from Figure 3 that VRBBON is comparable to NEWUOA in terms of efficiency and is more efficient than others. It is also more robust than others. In fact, the efficiency and robustness of VRBBON are higher when the standard initial points are used than when the shifted initial points are used, see Figure 4. Therefore, we used the shifted points for all test problems.

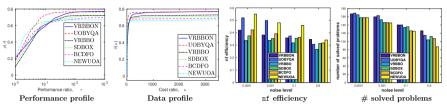

Fig. 3: For the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-1}, 0.9\}$ and small dimensions $1 < n \le 30$. The standard initial points are used. Details as in Figure 1.

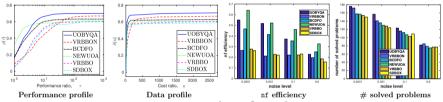

Fig. 4: For the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-1}, 0.9\}$ and small dimensions $1 < n \le 30$. The shifted initial points are used. Details as in Figure 1.

7.3.2 Medium scale: $30 < n \le 300$

For the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and medium scale problems $(30 < n \le 300)$, this section contains a comparison between VRBBON and the well-known direct search solvers, line search solvers, and matrix adaptation evolution solvers.

Figures 5 and 6 show in their subfigures, the cumulative (over all noise levels used) performance and data profiles in terms of the number of function evaluations and the other two plots show (the **nf** efficiency versus the noise level ω and the number of solved problems versus the noise level ω). From the subfigures of Figure 5, we conclude that VRBBON is more robust and efficient than the known direct search solvers. From the subfigures of Figure 6, we can also conclude that VRBBON is more robust and efficient than the known line search solvers and matrix adaptation evolution solvers at low and medium noise,

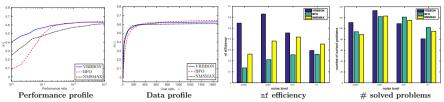

Fig. 5: Comparison between VRBBON and direct search solvers for the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and medium dimensions $30 < n \le 300$. Other details as in Figure 1.

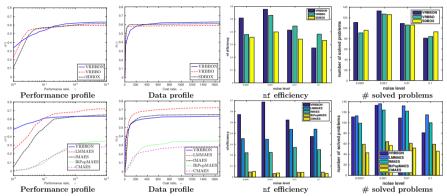

Fig. 6: Comparison between VRBBON and line search solvers (first row) and matrix adaptation evolution solvers solvers (second row) for the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and medium dimensions $30 < n \le 300$. Other details as in Figure 1.

while ${\tt LMMAES}$ is more robust than ${\tt VRBBON}$ and the other matrix adaptation evolution solvers at high noise.

Since the model-based solvers cannot handle problems in high dimensions, as described earlier, we denote UOBYQA in the random subspace by subUOBYQA and NEWUOA in the random subspace by subNEWUOA. Moreover, we denote NMSMAX in the random subspace by subNMSMAX.

The subfigures of Figure 7 show that VRBBON are much more efficient than others at low to high noise, but VRBBON are more robust than others at low noise, while subNEWUOA, subUOBYQA, and NMSMAX are slightly more robust than VRBBON only at high noise.

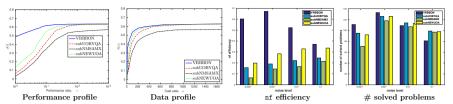

Fig. 7: Comparison between VRBBON and model-based solvers in a random subspace for the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and medium dimensions $30 < n \le 300$. Other details as in Figure 1.

7.3.3 Large scale: $300 < n \le 5000$

For the noise levels $\omega \in \{10^{-5}, 10^{-4}, 10^{-3}\}$ and large dimensions $300 < n \le 5000$, this section contains a comparison between VRBBON and the four effective solvers (VRBBO, LMMAES, and SDBOX) for problems in medium dimensions.

Figure 8 shows in its subfigures, the cumulative (over all noise levels used) performance and data profiles in terms of the number of function evaluations for the noise levels $\omega \in \{10^{-5}, 10^{-4}, 10^{-3}\}$ and the other two plots show (the nf efficiency versus the noise level ω and the number of solved problems versus the noise level ω). We conclude from these subfigures that VRBBON is slightly more efficient than others, while VRBBO and SDBOX are slightly more robust than VRBBON.

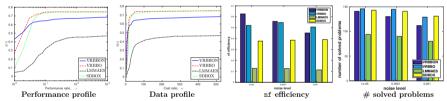

Fig. 8: Comparison between VRBBON and the effective solvers on the medium scale problems for the noise levels $\omega \in \{10^{-5}, 10^{-4}, 10^{-3}\}$ and large dimensions $300 < n \le 5000$. Details as in Figure 1.

7.4 Recommendation

Using Figures 8, 9, and 10, we have recommended which solvers are robust and which are efficient, depending on the noise level and dimension. Indeed, for small scale problems, Figure 9 is a comparison between five more robust and efficient solvers, and for medium scale problems, Figure 10 is a comparison between five more robust and efficient solvers. As shown in Subsection 7.3.1, Figure 8 is a comparison between four more robust and more efficient solvers.

Figure 11 is a Flow chart, classified by the problem dimension and the noise level, with the result that VRBBON is one of the three more robust and efficient solvers in most cases. Therefore, this solver is highly recommended for NBBOP.

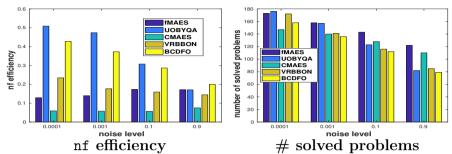

Fig. 9: Comparison between five more robust and efficient solvers for the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-1}, 0.9\}$ and small dimensions $1 < n \le 30$. Other details as in Figure 1.

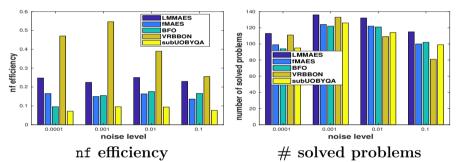

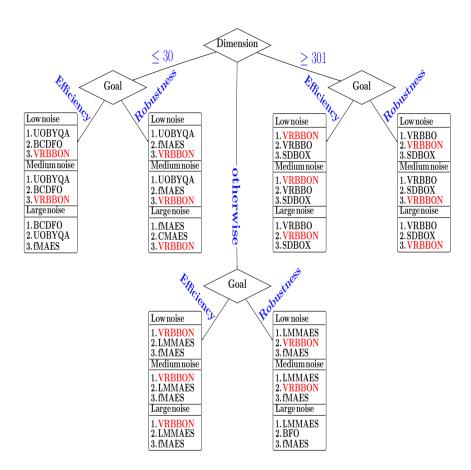

Fig. 10: Comparison between five more robust and efficient solvers for the noise levels $\omega \in \{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and medium dimensions $30 < n \le 300$. Other details as in Figure 1
